The Dual-Layer Economy
An Architectural Model for an Ecologically Sustainable and Financially Stable Civilization (Version 1.1)

Hanns-Steffen Rentschler
Independent Researcher, Germany
December 8, 2025

Abstract

This paper introduces the Dual-Layer Model (DLM), a macroeconomic system architecture designed to resolve a fundamental contradiction of modern economies: the need for an ecologically bounded, steady-state real economy alongside a financial system that remains structurally dependent on growth. The DLM separates the economy into a Real Economy layer (RE-layer) and a Synthetic Financial layer (SF-layer), connected by a strictly controlled interface.

1. Introduction

Modern economic systems face a structural deadlock between ecological limits and financial growth requirements. The Dual-Layer Model addresses this conflict through architectural separation.

2. The Structural Paradox

Material production is subject to physical limits, while finance relies on expansion. Their coexistence within a single system produces instability.

3. Architecture of the Dual-Layer Model

The Real Economy layer is ecologically bounded and focused on durability. The Synthetic Financial layer absorbs speculative growth under stability constraints.

3.1 Conceptual Separation of Economic Functions

The core premise of the Dual-Layer Model is that the instability of contemporary economies does not primarily arise from insufficient regulation, but from the forced coexistence of incompatible systemic logics within a single economic layer.

Material production, labor, and ecological systems follow fundamentally different constraints than financial markets, credit structures, and speculative asset dynamics. Treating both domains as if they could be governed by identical incentive mechanisms has resulted in recurring crises, environmental overshoot, and political fragility.

The Dual-Layer Model therefore rejects optimization within a unified system and instead applies architectural separation. Economic functions that are mutually destabilizing are assigned to distinct layers with explicitly different rules, constraints, and objectives.

3.2 The Real Economy Layer (RE-layer)

The Real Economy layer (RE-layer) encompasses all economic activity that directly interacts with physical reality. This includes the production of goods, provision of essential services, infrastructure maintenance, housing, food systems, energy supply, healthcare, and education.

The defining characteristic of the RE-layer is the presence of hard physical limits. Energy availability, material throughput, land use, and ecological regeneration rates impose non-negotiable constraints on long-term output. Consequently, the objective of the RE-layer is not growth, but stability, resilience, and quality.

Within the Dual-Layer Model, real output is explicitly capped by an ecological ceiling. Production is permitted only within a predefined resource envelope, reflecting planetary boundaries and sustainability targets. Investment in the RE-layer is therefore not expansionary, but qualitative: maintenance, efficiency improvements, durability, and substitution of resource-intensive processes.

Labor plays a central role in the RE-layer. Because labor is directly tied to social cohesion and material well-being, the canonical architecture eliminates taxation on labor income and consumption within this layer. Removing such taxes is not an incentive measure, but a design choice: it stabilizes purchasing power without increasing physical throughput.

3.3 The Synthetic Financial Layer (SF-layer)

The Synthetic Financial layer (SF-layer) is designed to absorb activities that exhibit inherent growth pressure but do not require proportional material expansion. This includes financial speculation, asset trading, algorithmic strategies, virtual goods, digital status economies, and large parts of AI-driven value creation.Unlike the RE-layer, the SF-layer operates primarily within informational and symbolic domains. While it is not costless in physical terms, its marginal resource footprint can be bounded and monitored independently from real production. Growth in the SF-layer is therefore not constrained by ecological scarcity, but by systemic stability.

In the Dual-Layer Model, the SF-layer is permitted to grow, but only within an explicit stability boundary. Asset expansion is limited through algorithmic controls that prevent runaway dynamics and systemic collapse. Importantly, growth in this layer is not treated as socially harmful per se; it is treated as neutral, provided its effects remain confined to the synthetic domain.

By providing a dedicated outlet for speculative and competitive pressures, the SF-layer serves as a pressure valve. It allows financial and technological dynamism to continue without transmitting volatility into the material foundations of society.

3.4 Functional Complementarity of the Two Layers

The Dual-Layer architecture does not assume antagonism between the RE-layer and the SF-layer. Instead, the two layers fulfill complementary systemic roles.

The RE-layer provides material stability, social cohesion, and ecological sustainability. The SF-layer absorbs excess growth demand, financial risk-taking, and non-material competition. Stability emerges not through moderation of individual behavior, but through confinement of each logic to an appropriate domain.

Critically, neither layer is self-sufficient. The RE-layer benefits from public investment financed through controlled extraction of value from the SF-layer. The SF-layer relies on the RE-layer for legitimacy, institutional support, and the conversion of synthetic gains into real public goods.

This relationship is deliberately asymmetric: while synthetic growth may occur freely within its own domain, access to the real economy is strictly mediated. This asymmetry is the central stabilizing feature of the model.

3.5 Architectural Neutrality

The Dual-Layer Model is intentionally neutral with respect to political systems, cultural norms, and ideological preferences. Its architecture does not assume particular behavioral changes, moral commitments, or redistributive ethics.

Instead, stability arises from structural constraints. Actors may pursue profit, status, or growth within the SF-layer without threatening ecological or social foundations. Likewise, the RE-layer can remain stable without requiring continuous expansion or austerity.

By shifting the focus from regulation to architecture, the model reframes economic policy as system design rather than behavior management.

4. Interface, Firewall, and Non-Circumventability

4.1 The Interface as a Structural Constraint

In the Dual-Layer Model, the interface between the Real Economy layer (RE-layer) and the Synthetic Financial layer (SF-layer) is not treated as a regulatory boundary, but as a structural property of the system. The separation between both layers is not enforced through behavioral rules, compliance requirements, or political discretion, but through the design of the monetary and transactional infrastructure itself.

This distinction is fundamental. Regulatory frameworks are inherently vulnerable to lobbying, reinterpretation, and gradual erosion. Architectural constraints, by contrast, shape the space of possible actions independently of individual incentives. The Dual-Layer Model therefore assigns the burden of enforcement to the system architecture rather than to institutions or actors.

4.2 Monetary Non-Equivalence of the Layers

A central feature of the model is the strict non-equivalence of monetary units across layers. Currency used within the RE-layer and assets circulating within the SF-layer are defined as different financial objects, with no automatic convertibility.

RE-layer currency represents claims on physical goods, labor, and real services. SF-layer assets represent claims on synthetic positions, algorithmic strategies, or virtual value. Treating both forms of value as interchangeable would reintroduce the very instability the model seeks to eliminate.

Consequently, SF-assets cannot be used directly to purchase real goods or labor. Likewise, RE-currency cannot be deployed for speculative purposes within the SF-layer. This non-equivalence is not semantic but technical.

4.3 The Firewall: One-Way Permeability

The interface between the two layers is deliberately asymmetric.

Capital flows from the RE-layer into the SF-layer are structurally prohibited. There is no legal, regulatory, or contractual path by which real-economy currency can be transformed into speculative purchasing power. This eliminates capital flight, shadow banking, and indirect financialization of real production at the architectural level.

Flows from the SF-layer into the RE-layer are permitted only through predefined, system-wide mechanisms. Private conversion of synthetic income into real purchasing power is subject to automatic taxation. Public transfers from the SF-layer into the RE-layer occur only in the form of explicitly authorized investments in infrastructure, maintenance, or collective goods.

This one-way permeability ensures that speculative dynamics can never exert upward pressure on real-economy demand or prices.

4.4 Technical Enforcement Without Discretion

While the exact technological implementation is not the focus of this paper, the model assumes that enforcement is achieved through digital monetary infrastructure. Central-bank issued digital currency and smart-contract-based transaction rules provide a feasible implementation pathway.

Crucially, enforcement is automatic. Transactions violating layer separation are not illegal acts subject to punishment; they are system-invalid states that cannot be executed. No authority has discretionary power to grant exceptions, approve special cases, or retroactively reinterpret the rules.

In this sense, the model follows a “code-based” logic of enforcement rather than a legal-procedural one. This does not eliminate the need for political institutions, but it sharply limits the domain in which discretionary power can destabilize the system.

4.5 Elimination of Circumvention Pathways

Because the firewall operates at the monetary and transactional level, common circumvention strategies lose their effectiveness. Financial innovation, regulatory arbitrage, and cross-border capital structures cannot bridge the layers if no exchange path exists at the currency level.

Shadow markets cannot substitute for missing convertibility, as synthetic assets have no purchasing power within the RE-layer unless they pass through the system-defined interface. Likewise, political capture of regulatory agencies cannot reintroduce permeability without a fundamental redesign of the system architecture.

The result is not perfect enforcement, but a qualitative shift in the nature of violations: from profitable circumvention to futile attempts at bypassing non-existent interfaces.

4.6 Political Neutrality and Systemic Robustness

The Dual-Layer Model does not rely on democratic norms, authoritarian control, or cultural compliance to function. Its core stabilizing mechanisms are indifferent to regime type, administrative capacity, or ideological orientation.

As long as the architectural separation of layers and the associated firewall remain intact, the model produces stability as an emergent property. Political systems may vary; the architecture remains.

This neutrality is essential for the model's global applicability and long-term resilience.

5. Tax Architecture and Policy Space

5.1 The Single-Tax Principle

The tax architecture of the Dual-Layer Model follows a strict single-tax principle. In its canonical form, all public revenue is raised exclusively through taxation of synthetic income generated within the SF-layer. No taxes are levied on labor income, real consumption, or real investment within the RE-layer.

This design choice is not motivated by normative preferences regarding redistribution or incentives. It follows directly from the architectural separation of layers. Since the RE-layer is ecologically constrained and non-expansionary by design, taxing labor or consumption within this layer would reduce real purchasing power without contributing to systemic stability.

Conversely, synthetic income is generated in a domain where growth is permitted and socially non-essential. Taxing this income does not affect material supply, ecological pressure, or the productive capacity of the real economy.

5.2 Taxation as an Interface Mechanism

Within the Dual-Layer Model, taxation serves a dual function. It is not only a fiscal instrument but also an interface control between layers.

Private conversion of synthetic income into real purchasing power is automatically taxed at a high rate upon transfer from the SF-layer to the RE-layer. This ensures that speculative gains cannot translate into proportional increases in real consumption or private accumulation of real assets.

In this sense, the synthetic-income tax is not primarily redistributive. It acts as a damping mechanism that neutralizes the wealth effect typically associated with financial booms. The precise tax rate is a policy parameter, but its qualitative role is structural: it decouples speculative dynamics from real demand.

5.3 Elimination of Labor and Consumption Taxes

In the baseline architecture, labor income taxes are set to zero. Real consumption is likewise untaxed. This configuration increases net real wages and stabilizes household purchasing power within the ecological envelope of the RE-layer.

Importantly, this increase in purchasing power does not translate into increased material throughput. Since real output is capped, higher net wages primarily affect distribution and security rather than aggregate production. The model therefore allows for social stabilization without violating ecological constraints.

By removing taxes on labor and consumption, the Dual-Layer Model avoids the common policy trade-off between employment, public revenue, and sustainability.

5.4 Policy Space and Contingent Adjustment

Although the single-tax principle defines the canonical architecture, the model intentionally preserves limited policy space. In the numerical implementation, a labor-tax parameter is retained, but set to zero in all baseline simulations.

This serves two purposes. First, it allows the exploration of contingency scenarios in which synthetic-tax revenue may be temporarily insufficient, for example due to transitional dynamics or external shocks. Second, it demonstrates that the model's stability does not rely on hidden fiscal assumptions.

Crucially, this policy flexibility operates entirely within the RE-layer and does not compromise the firewall between layers. Any temporary labor taxation is treated as a stabilizing fallback mechanism rather than a permanent revenue source.

5.5 Public Revenue, Debt Reduction, and Investment

Revenue from the synthetic-income tax accrues directly to the public sector. In the model simulations, these revenues are sufficient to eliminate budget deficits and enable sustained reduction of public debt, even in the absence of labor taxation.

Beyond debt reduction, public revenue is used to finance maintenance, infrastructure renewal, and efficiency-enhancing investment in the RE-layer. Because such investments do not increase material throughput, they strengthen system resilience rather than growth.

The tax architecture thus transforms speculative volatility into a stabilizing fiscal resource without requiring behavioral intervention or continuous political calibration.

5.6 Taxation Without Redistribution Narratives

The Dual-Layer Model deliberately avoids framing its tax architecture in terms of fairness, punishment, or redistribution. Synthetic-income taxation is justified solely by its systemic function.

This neutrality is essential for the model's political robustness. It allows the architecture to operate under diverse ideological regimes while maintaining its stabilizing properties. The tax system is not a tool for moral correction, but a structural component of the economic design.

6. Methodology: Stock-Flow Consistent Modeling

6.1 Rationale for a Stock-Flow Consistent Approach

To evaluate the internal coherence and dynamic stability of the Dual-Layer Model, a Stock-Flow Consistent (SFC) modeling framework is employed. SFC models are particularly suited for this purpose because they enforce strict accounting consistency between flows and stocks across all sectors of the economy.

Unlike partial-equilibrium or representative-agent models, the SFC approach ensures that every financial flow corresponds to a change in at least one balance sheet position. This feature is essential for assessing architectures that rely on controlled interfaces between economic domains, as it prevents hidden leakages or implicit assumptions about financing.

The use of an SFC framework therefore aligns methodologically with the architectural focus of the Dual-Layer Model.

6.2 Sectoral Structure of the Model

The implemented model distinguishes four aggregated sectors:

1. Households, earning labor income in the RE-layer and holding both real monetary balances and synthetic assets.
2. Real-Economy Firms (RE-firms), producing goods and services within an ecological production constraint.
3. Synthetic Financial Sector (SF-sector), generating synthetic income through asset growth and speculative activity.
4. Government, collecting taxes, providing transfers, and conducting public investment.

Each sector maintains explicit stock variables (such as capital, wealth, assets, and public debt) and flow variables (such as income, consumption, taxation, and investment). All transactions between sectors are recorded symmetrically, ensuring balance-sheet closure at every time step.

6.3 Modeling the Two Layers

The dual-layer architecture is reflected directly in the model structure.

The RE-layer is modeled as a steady-state production system. Real output depends on the existing capital stock and an exogenously specified ecological resource ceiling. Investment in this layer is restricted to maintenance and efficiency improvements and does not generate sustained growth in output.

The SF-layer is modeled as a synthetic asset system with internally generated growth dynamics. Asset expansion follows a bounded growth process, capturing speculative booms while preventing unbounded divergence. Importantly, synthetic assets do not enter real production functions and cannot be directly exchanged for real goods.

This explicit separation ensures that instability in one layer cannot propagate mechanically into the other.

6.4 Interface Representation in the Model

The interface between layers is represented through explicit flow restrictions.

Flows from the RE-layer into the SF-layer are excluded by construction. Households cannot allocate real monetary balances to speculative assets. Conversely, flows from the SF-layer into the RE-layer are mediated through two channels only: taxation of synthetic income and controlled public transfers.

Private synthetic income is subject to automatic taxation upon conversion, reducing the effective wealth effect on real consumption. Public transfers from the SF-layer to the RE-layer are delayed and limited, representing long-term public investment rather than immediate demand stimulus.

These constraints replicate the firewall mechanism at the level of financial accounting rather than legal enforcement.

6.5 The Wealth Effect as a Stress Variable

A central objective of the simulations is to test whether the Dual-Layer architecture can neutralize the wealth effect typically observed during financial booms. The wealth effect is modeled as the propensity of households to convert financial gains into real consumption.

To create a stringent stress test, this parameter is deliberately set to an unusually high level. In the absence of layer separation or taxation, such a configuration would generate explosive demand pressure in the real economy.

By fixing behavioral parameters and modifying only the architectural rules at the interface, the model isolates the stabilizing contribution of the Dual-Layer design itself.

6.6 Baseline Configuration and Policy Parameters

In the baseline scenario reported in this paper, labor income taxation is set to zero, reflecting the single-tax architecture. A synthetic-income tax is applied at the interface between layers. All simulations assume identical behavioral parameters across scenarios.

The presence of additional policy parameters, such as a dormant labor-tax variable, does not imply multi-taxation in the baseline configuration. These parameters are retained solely to explore contingency scenarios and to demonstrate that the model's stability does not rely on hidden assumptions.

6.7 Scope and Limitations

The model is not intended as a forecasting tool. Its purpose is architectural validation: to test whether the proposed separation of layers is sufficient to prevent instability under extreme conditions.

Accordingly, numerical values are chosen for transparency and stress testing rather than empirical calibration. The results should be interpreted qualitatively, focusing on system behavior and internal consistency.

7. Simulation Results

7.1 Analytical Focus

The simulation analysis focuses on a single critical transmission channel: the wealth effect. In conventional economic systems, increases in financial wealth tend to translate rapidly into higher real consumption. Under ecological constraints, such demand pressure results in inflationary dynamics, rising private debt, and ultimately systemic instability.

The Dual-Layer Model claims to neutralize this mechanism not by altering household behavior, but by structurally isolating speculative income from real purchasing power. The simulations therefore deliberately apply extreme conditions to test this claim.

7.2 Stress Scenario Without Interface Control

As a reference case, the model is simulated without taxation of synthetic income and without effective interface control. In this configuration, households are allowed to convert a large share of synthetic income into real consumption. The wealth-effect parameter is set to an unusually high value to represent aggressive speculative exuberance.

Under these conditions, real consumption demand rises sharply following asset growth in the synthetic layer. Because real output is capped by the ecological ceiling, supply cannot respond. The resulting excess demand is financed through declining household money balances and increasing indebtedness.

The system rapidly becomes unstable. Real household wealth deteriorates, public finances weaken, and the real economy is exposed to the full volatility of speculative dynamics. This outcome replicates the familiar boom-bust patterns observed in financialized economies.

7.3 Stabilization Scenario With Single Tax and Firewall

The baseline Dual-Layer configuration applies automatic taxation to synthetic income at the point of conversion into the real economy, while leaving behavioral parameters unchanged. Labor income taxation is set to zero.

Despite identical speculative dynamics in the synthetic layer, real consumption remains stable. The strong wealth effect at the behavioral level does not materialize at the macro level because synthetic gains lose their purchasing power before they can reach real markets.

Real output remains close to its steady-state level, bounded by ecological constraints. Household purchasing power derived from labor income is higher and more stable due to the absence of labor taxation. Importantly, this stability is achieved without suppressing or regulating speculative activity itself.

7.4 Government Balance and Public Debt Dynamics

A central result of the simulations concerns public finance. In the stabilization scenario, synthetic-income taxation generates substantial and countercyclical public revenue. Even as labor taxes are eliminated, total government revenue increases.

As a consequence, public deficits are eliminated and public debt is reduced over time. This occurs without austerity measures, reduction of public services, or increases in real-economy taxation. Speculative volatility is effectively converted into fiscal stability.

The state thus gains financial capacity precisely when speculative activity intensifies, reversing the pro-cyclical vulnerability common in current systems.

7.5 Decoupling of Layers Under Extreme Conditions

The most important qualitative result is the effective decoupling of the two layers. Extreme fluctuations in the synthetic asset stock do not propagate into the real economy. Real consumption, real output, and real household wealth remain stable despite large asset booms.

This decoupling does not depend on moderate behavior, rational expectations, or credibility assumptions. It is achieved solely through architectural constraints at the interface between layers.

7.6 Robustness of the Architecture

The simulations demonstrate that the stability of the Dual-Layer Model is robust with respect to behavioral stress. Even implausibly strong wealth effects fail to destabilize the real economy when the architectural separation is in place.

This suggests that the model's stabilizing properties arise from system design rather than from parameter tuning. The architecture converts potentially destabilizing dynamics into contained fluctuations within the synthetic layer.

8. Discussion and Limitations

8.1 Architectural Scope and Interpretation

The Dual-Layer Model is not presented as a complete macroeconomic theory, nor as a detailed implementation blueprint. Its primary contribution lies at the level of system architecture. The model explores whether a strict functional separation of economic domains is sufficient to resolve structural instabilities that persist under a wide range of regulatory and behavioral approaches.

As such, the model should be interpreted as an architectural feasibility study rather than a policy prescription. Its validity does not depend on precise parameter calibration, but on the internal coherence of its design principles.

8.2 Implementation Assumptions

The model assumes the existence of transactional infrastructure capable of enforcing layer separation. While digital currency systems and automated transaction rules provide a plausible implementation pathway, real-world deployment would require substantial institutional coordination and political commitment.

The paper deliberately abstracts from transitional dynamics, distributional conflicts, and legacy financial structures. These issues are critical in practice but orthogonal to the architectural question addressed here: whether separation, once established, produces stability.

8.3 Technology, Governance, and Control

Although the model relies on code-based enforcement, it does not imply a preference for technocratic governance or reduced political oversight. The architecture constrains certain interactions, but leaves distributional decisions, public spending priorities, and social policy fully within the political domain.

Nevertheless, the concentration of enforcement power in digital infrastructure raises legitimate concerns regarding transparency, accountability, and abuse. These concerns are not unique to the Dual-Layer Model but are inherent to any system that seeks credible enforcement of macroeconomic constraints.

8.4 Power, Distribution, and Inequality

The Dual-Layer Model does not directly address questions of income inequality or wealth concentration within the synthetic layer. It limits the transmission of such inequalities into the real economy but does not eliminate disparities within the synthetic domain itself.

This design choice is intentional. The model prioritizes systemic stability and ecological sustainability over distributive optimization. Redistribution, where desired, can be implemented through political mechanisms using public revenue generated at the interface.

8.5 Behavioral and Cultural Factors

The model does not rely on changes in individual behavior, social norms, or moral incentives. While such factors may influence long-term outcomes, they are not required for stability within the proposed architecture.

This abstraction is both a strength and a limitation. It enhances robustness but may understate the role of cultural acceptance in real-world adoption.

8.6 External Validity

The Dual-Layer Model is designed to be politically neutral and applicable across different governance systems. However, its effectiveness depends on the integrity of the architectural separation. Partial implementation or politically motivated erosion of the firewall would undermine its stabilizing properties.

The model therefore highlights a broader challenge in macroeconomic design: stability depends not only on rules, but on the credibility of the structures that enforce them.

9. Conclusion

This paper has presented the Dual-Layer Model as an architectural response to a persistent structural contradiction of modern economies: the incompatibility between ecological limits in the real economy and growth dependence in financial systems.

Rather than attempting to reconcile these opposing logics within a single institutional framework, the model proposes a functional separation into a bounded Real Economy layer and a growth-tolerant Synthetic Financial layer. Stability emerges not from behavioral discipline or regulatory fine-tuning, but from the confinement of incompatible dynamics to distinct domains.

Stock-Flow Consistent simulations demonstrate that this architectural separation effectively neutralizes the transmission of speculative volatility into real consumption and production. Even under extreme behavioral assumptions, the real economy remains stable, public debt can be reduced, and labor income remains untaxed without fiscal fragility.

The central contribution of the Dual-Layer Model lies in reframing macroeconomic stability as a problem of system design rather than incentive management. Ecological sustainability and financial stability are not treated as trade-offs, but as properties of different layers within a coherent architecture.

Whether such a system can be realized in practice is ultimately a political question. Whether it is internally consistent and capable of delivering stability under stress is an architectural one. This paper provides evidence that, under its stated assumptions, such an architecture is feasible.

10. Appendix A: Core Equations of the Dual-Layer Model

This appendix summarizes the core relationships of the Dual-Layer Model in informal mathematical notation. Subscript R refers to the real-economy layer, S to the synthetic layer. Superscript H denotes households, G denotes government. Time is discrete (t = 0, 1, 2, …).

10.1 Real-Economy Production

Real output in the RE-layer is constrained by an ecological ceiling:

Y_R_max denotes the maximal feasible real output implied by the ecological resource ceiling.

- Production function (Cobb–Douglas, with ecological cap):

Y_R(t) = min(F(K_R(t-1), R_max), Y_R_max)

with

F(K_R, R) = K_R^0.6 * R^0.4

K_R(t) is the real capital stock, R_max the ecological resource ceiling.

10.2 Income Distribution in the Real Economy

Real output is split into wages and profits:

- Wage income:

W_R(t) = alpha_W * Y_R(t) (e.g. alpha_W = 0.7)

- Profit income:

Profits_R(t) = (1 - alpha_W) * Y_R(t)
Labor income tax is represented by a parameter tau_labor:

T_R_H(t) = tau_labor * W_R(t)

In the baseline architecture:

tau_labor = 0.0

so that

W_R_net(t) = W_R(t) - T_R_H(t) = W_R(t)

Households also receive transfers:

Tr_R(t) = Tr_bar (constant basic transfer)

10.3 Synthetic Asset Dynamics (SF-Layer)

The synthetic asset stock A_S follows bounded (logistic) growth:

Delta_A_S_total(t) = lambda * A_S_total(t-1) * (1 - A_S_total(t-1) / Omega)

A_S_total(t) = A_S_total(t-1) + Delta_A_S_total(t)

Synthetic income is identified with asset growth:

Y_S_total(t) = Delta_A_S_total(t)

Households hold a share of synthetic assets; their synthetic income Y_S_H(t) is proportional to their share:

Y_S_H(t) = Y_S_total(t) * (A_S_H(t-1) / A_S_total(t-1))

(if A_S_total(t-1) > 0, otherwise Y_S_H(t) = 0)

10.4 Single-Tax Mechanism at the Interface

The single-tax principle is implemented as a tax on synthetic income at the point of conversion into the RE-layer:

- Synthetic-income tax:

T_SF(t) = tau_SF * Y_S_H(t)

with a high tax rate, e.g.

tau_SF = 0.9

- Net synthetic income:

Y_S_H_net(t) = Y_S_H(t) - T_SF(t)
In the canonical architecture, this is the only operational tax in steady state; tau_labor = 0.0 in all baseline simulations.

10.5 Household Consumption and Wealth

Real consumption C_R(t) depends on net wages, net synthetic income, and real money balances:

C_R(t) = c1 * W_R_net(t) + c2 * Y_S_H_net(t) + c3 * M_R_H(t-1)

with:

- c1 = propensity to consume out of wages
- c2 = propensity to consume out of synthetic income (wealth effect)

- c3 = propensity to consume out of real money balances

Household real money balances evolve as:

M_R_H(t) = M_R_H(t-1)
+ W_R_net(t)
+ Tr_R(t)
+ Y_S_H_net(t)
- C_R(t)
- Delta_A_S_H(t)

where Delta_A_S_H(t) is the portion of net synthetic income reinvested into synthetic assets:

Delta_A_S_H(t) = psi * Y_S_H_net(t)

A_S_H(t) = A_S_H(t-1) + Delta_A_S_H(t)

10.6 Capital Accumulation in the Real Economy

The RE-layer capital stock evolves according to maintenance and efficiency investment:

I_Erhalt(t) = delta * K_R(t-1)

I_Effizienz(t) = gamma * max(R_eff_ziel - R_eff_aktuell(t), 0)

Total real investment:

I_R(t) = I_Erhalt(t) + I_Effizienz(t)

Capital update:

K_R(t) = K_R(t-1) + I_R(t) - delta * K_R(t-1)

10.7 Government Budget and Public Debt

Total tax revenue:

T_R_total(t) = T_R_H(t) + T_SF(t)

Government real spending is split into basic spending and investment funded from the SF-layer:

G_R_basis(t) = G_bar (constant baseline spending)

T_SF_RE(t) = tau * Y_S_H_lagged(t) (time-delayed transfer from SF to RE)

G_R_Invest(t) = T_SF_RE(t)

Total government expenditure:

G_R(t) = G_R_basis(t) + G_R_Invest(t)

Deficit:

Defizit_G(t) = G_R(t) + Tr_R(t) - T_R_total(t)

Public debt evolves as:

B_G(t) = B_G(t-1) + Defizit_G(t)

11. Appendix B: Python Simulation Code (Version 1.1)

The following Python code implements the Stock-Flow Consistent model described in Sections 6 and 7. All parameters correspond to the baseline scenario discussed in the text.

```

Version History

Version 1.1 — December 2025

Version 1.1 constitutes a structural clarification and formal consolidation of the original architectural proposal. The core logic of the Dual-Layer Model remains unchanged. The following substantive revisions were made:

1. Explicit Single-Tax Architecture
   The tax system is clarified as a single-tax model. All public revenue in the canonical architecture is raised exclusively through taxation of synthetic income at the interface between layers. Labor and consumption taxes in the real economy are explicitly set to zero in the baseline configuration.

2. Clarification of Policy Parameters
   A labor-tax parameter is retained in the formal model and code but fixed at zero in all baseline simulations. Its presence is explicitly justified as a policy contingency mechanism for scenario analysis rather than an operative revenue source.

3. Formalization of the Firewall Mechanism
   The interface between the real economy and the synthetic financial layer is reformulated as a non-circumventable architectural constraint rather than a regulatory rule. The role of digital transaction infrastructure is clarified as an enforcement pathway, not as a technological claim.

4. Expanded Methodological Section
   The Stock-Flow Consistent framework is described in greater detail, with explicit emphasis on architectural validation, balance-sheet closure, and stress testing under extreme behavioral assumptions.

5. Extended Simulation Documentation
   The simulation section is expanded to distinguish explicitly between uncontrolled transmission scenarios and the stabilized Dual-Layer configuration. The role of the wealth effect as a stress variable is made explicit.

6. Addition of Formal Appendices
   A mathematical appendix summarizing the core equations and a full Python code appendix enabling replication have been added to ensure transparency and reproducibility.

7. Structural and Editorial Refinement
   The paper has been reorganized for clarity, terminology has been standardized, and narrative emphasis has shifted from normative interpretation to architectural feasibility.

Author’s Note

This paper is presented as a working paper and architectural feasibility study. Its primary purpose is not to offer short-term policy prescriptions or empirical forecasts, but to explore whether a strict functional separation between material economic activity and synthetic financial dynamics can resolve persistent structural instabilities observed in modern economies.

The Dual-Layer Model developed here deliberately operates at a high level of abstraction. Numerical simulations are used exclusively to test internal coherence and dynamic stability under extreme stress conditions, not to calibrate the model to specific empirical economies. Parameter values are therefore chosen for transparency and robustness rather than realism. The results should be interpreted qualitatively, with the focus on system behavior rather than point estimates.

The author does not claim novelty with respect to individual components of the model. Concepts such as ecological limits, steady-state economics, financial instability, and stock-flow consistency are well established in the literature. The contribution of this paper lies in their architectural integration and in the explicit treatment of the interface between real and synthetic economic domains as a non-circumventable system property rather than a regulatory choice.

The simulations included in this paper are intentionally conservative in their assumptions about behavior. No reliance is placed on rational expectations, moral incentives, or behavioral change. Stability, where it emerges, is produced solely by structural constraints imposed at the system level. This design choice reflects the author’s conviction that long-run macroeconomic stability cannot depend on persistent behavioral discipline.

The author has no institutional affiliation and writes in an independent capacity. This paper should therefore be understood as an open contribution to ongoing debates in ecological economics, financial stability, and macroeconomic system design. All assumptions, equations, and source code are provided transparently to facilitate critique, replication, and extension.

Comments, criticism, and alternative implementations are explicitly invited. In particular, the author welcomes discussion on potential transition paths, institutional requirements, and political constraints that lie beyond the scope of the present architectural analysis.
